(54) Optoelectronic devices.

(57) The present invention is directed to novel op-
toelectronic devices, such as light emitters and de-
tectors, that have a unique combination of semicon-
ductor materials that provides a band arrangement
resulting in improved efficiency of carrier injection.
The devices are quantum well type devices in which
discrete electronic states are formed by size quan-
tization effects in the quantum well region. Elec-
tromagnetic radiation of emission and absorption oc-
curs by the transition of electrons from a first energy
state to a second energy state in either the conduc-
tion band or the valence band of the quantum well
layer (12). The bands edges of the layers are offset
such that under an appropriate bias, the discrete
energy states reside in the bandgap of one of the
electrodes (14) and in an allowed region of the other
electrode (16), with one state residing in the conduc-
tion band of one electrode and the other state resid-
ing in the valence band of the other electrode. The
wavelength of the emitted or detected light is in-
versely proportional to the energy difference be-
tween the first and second states. Wavelength
customization is facilitated by techniques for adjust-
ing the energy difference.

OPTOELECTRONIC DEVICES

The present invention is directed to semiconductor optoelectronic devices and more particularly, to quantum well semiconductor optoelectronic devices having improved carrier injection efficiency and wavelength tuning.

Optoelectronic devices, such as lasers, light emitting diodes and light detectors, are useful in a wide range of applications, including communications systems, surgical instruments, and various electronic devices. Semiconductor optoelectronic devices are based upon the excitation and recombination of charge carriers in a semiconductor material. One such semiconductor optoelectronic device is a quantum well device, wherein a thin layer of semiconductor material, the quantum well active region, is sandwiched between layers of another semiconductor that serve as the sources of charge carriers that are injected into the quantum well. The cladding injection layers have a wider bandgap than the active layer and the quantum well layer is made very thin in order to form discrete energy levels in the active layer by the size quantization effect. In order to emit or absorb light, a quantum transition occurs between the conduction band and the valence band of the active region. Electrons are injected into the active region from one cladding layer and holes are injected into the active region from the other cladding layer. The electrons and holes recombine in the active region resulting in the emission of electromagnetic radiation.

There has been significant interest in developing techniques for improving the efficiency of such devices. The interest has focused on increasing the efficiency of carrier injection into the quantum well and recombination within the quantum well and also to providing wavelength tuning. In addition, it is also desirable to provide efficient device operation at wavelengths in the range of 1.3-10 μm, currently of interest for optical communications.

One recent development in quantum well light-emitting technology being explored is resonant tunnelling in superlattice regions. In resonant tunnelling, minibands of the superlattice active region are aligned with energy levels in the cladding injector layers so that carriers tunnel through barrier layers from the injector layer to the collector layer at a single energy level. Helm et al., Physical Review Letters, Vol. 63(1) 1989, disclose sequential resonant tunnelling to provide intersubband emission from semiconductor superlattices. Yuh et al. in Appl. Phys. Lett. 51(18) 1987, disclose a band aligned superlattice laser in which an active region is formed with two minisubbands, the upper minisubband being aligned with the minisubband of the emitter region and the lower minisubband being

aligned with the minisubband of the collector region. While carrier injection is apparently improved, there is extreme dependence on the formation of the superlattice layers which must be very precise in order to provide the alignment of the manmade minibands.

The invention as claimed is intended to remedy these drawbacks.

The present invention is directed to semiconductor optoelectronic quantum well devices having a unique relationship of band energies of the semiconductor layers which provides a novel way of realizing efficient carrier injection and customization to a broad range of wavelengths. The devices are formed by a quantum well active region sandwiched between cladding electrode layers that are separated from the active region by thin tunnelling regions and/or by potential barriers. Thus, the devices may comprise three, four or five layers of semiconductor material. The quantum well active region contains at least two electronic states formed by the size-quantization effect. Under an operating bias voltage, each energy state resides in the forbidden region of one of the electrodes and simultaneously in the allowed region of the other electrode. One of the states resides in the conduction band of one electrode and the other state resides in the valence band of the other electrode.

The optoelectronic devices of the present invention are adaptable for electromagnetic energy emission or absorption. Thus, depending on the relationship of the band energies of the various materials used to form the layers, the resulting structures are capable of emitting or absorbing light from the near to the far infrared. In the active region, the energy states are spaced apart in either the conduction band or the valence band. The optical transitions, emission or absorption, take place between a pair of energy states. The difference in energy between the two states determines the frequency of the emitted or absorbed electromagnetic energy. If the optical transition takes place in the conduction band, the transition is between electron states. If the optical transition takes place in the valence band, the transition is between hole states.

For a light emitting device under bias, the higher electronic state resides in the conduction band of the emitter electrode and simultaneously resides in the bandgap of the collector electrode. The lower electronic state simultaneously resides in the bandgap of the emitter electrode and in the valence band of the collector electrode. To emit light, the structure is forward biased so that carriers are injected from the emitter electrode to the high-

er energy state in the active region. These carriers cannot travel directly to the collector electrode at that high energy level because the energy level resides in the bandgap of the collector layer. The carriers relax to the lower energy state thereby causing light to be emitted at a wavelength inversely proportional to the difference in energy of the two states. At the lower energy level, which lies in the valence band of the collector region, the carriers then travel through to the collector layer. The carriers are prevented from travelling back to the emitter electrode because the lower energy level resides in the bandgap of the emitter electrode.

For a light detecting device, the band edge arrangement is the same as the light emitter under an operating bias voltage. However, there is a difference in the material requirements in that in equilibrium, the Fermi level of the light-detecting device must be in the bandgap of either of the cladding electrodes. This difference in Fermi level alignment is necessary to allow a negative bias to be applied to the detector. Under an operating negative bias, the path for electrons is limited due to the energy band arrangement to being injected from the collector into the lower energy state in the quantum well. Absorption of light within the proper wavelength range will cause the electrons in the lower state to be excited to the higher energy level where they will flow to the emitter.

The devices may be implemented with a combination of type I and/or type II tunnel heterojunctions that use more than two different materials, forming polytype hetero-structures. In these embodiments, a thin tunnel barrier is provided between one or both of the cladding electrodes and the active region so that carriers are injected into the quantum well by tunnelling. In another embodiment, the devices are implemented with a combination of type I and/or type II heterojunctions in which carrier injection occurs through potential barriers at one or both of the electrode-active region interfaces.

The devices of the present invention operate in a more efficient manner than the minority-carrier injection of forward-biased pn junctions used in conventional semiconductor light-emitting devices and laser diodes, since there is no minority carriers involved in the operation of the inventive devices. In addition, the present invention differs drastically from the conventional resonant-tunnelling schemes. The present invention provides a system in which efficient carrier injection may be more easily realized and which also facilitates customization to a broad range of wavelengths. Various known techniques may be employed to vary the spacing between the energy states in the quantum well to provide the desired wavelength for light emission or absorption.

For a better understanding of the present invention, together with further objects and advantages, the invention is described in the following with reference to the accompanying drawings, in which:

Figs. 1a and 1b
are examples of energy band profiles for the light emitting devices of the present invention, wherein Fig. 1a shows the equilibrium state and Fig. 1b shows the biased state;

Fig. 2
is an energy band profile of a specific embodiment of the light emitting device of the present invention in a biased state;

Figs. 3a and 3b
are examples of energy band profiles of the light detecting devices of the present invention, wherein Fig. 3a shows the equilibrium state and Fig. 3b shows the biased state; and

Fig. 4
is an energy band profile of a specific embodiment of the light detecting device of the present invention in a biased state.

Referring now to the drawings, Figures 1a and 1b depict energy band profiles for the light emitting devices of the present invention. The profiles shown in Figures 1a and 1b, as well as in Figures 3a and 3b, are general in nature and are designed to portray the basic concept of the invention. The band edges for all of the layers are not shown, as only the area of interest for the structures is depicted. The band edges not shown may vary for particular material systems, but their general relationship with the shown edges will be described. In addition, all the figures depict five layer devices but it will be understood by those skilled in the art that the energy band profiles will be identical for three and four layer devices with the energy band for either one or both of the electrodes being shifted to be adjacent to the active region in the absence of a barrier layer.

Turning now to Figure 1a, there is shown a five layer light emitting device 10 in equilibrium, comprised of a quantum well region 12 sandwiched between a first cladding electrode 14 and a second cladding electrode 16. Electrode 14 is separated from the quantum well region 12 by tunnel barrier 18 and electrode 16 is separated from the quantum well region 12 by tunnel barrier 20. In the quantum well region 12, a plurality of energy states are formed by the size-quantization effect. In order to provide the necessary carrier confinement to form the discrete energy levels, tunnel barriers 18 and 20 must have a wider bandgap than the bandgap of the active region 12. As shown in Figure 1a, two energy states E_1 and E_2 are formed. It should be understood that the band edge of the active region

12 is not shown because the energy states E_1 and E_2 may be formed in either the conduction band or the valence band of layer 12. If the energy states are in the conduction band, the conduction band edge will be below E_1. Alternatively, if the energy states are in the valence band, the valence band edge will be above E_2.

Barrier layers 18 and 20 are tunnel barriers such that the bandgap must be wide enough so that the layers act like insulators and also thin enough so that carriers can tunnel through the layers. In the illustrative embodiment shown in Figure 1a, in the equilibrium or unbiased condition, the light emitting device is formed with the energy state E_1 residing in the bandgap of electrode 14 and simultaneously in the valence band of electrode 16. Energy state E_2, resides simultaneously in the conduction band of electrode 14 and the bandgap of electrode 16. Alternative equilibrium band edge arrangements are also possible such as where both E_1 and E_2 resides only in allowed regions of the electrodes 14 and 16.

As shown in Figure 1b, under an appropriate forward bias voltage V_b, i.e., electrode 16 biased positively with respect to electrode 14, the alignment of the bands is such that electrons will tunnel from the conduction band of layer 14 through layer 18 to energy state E_2. The electrons in state E_2 are prevented from tunnelling directly through to layer 16 because state E_2 resides in the bandgap of layer 16. Arrow 22 depicts the tunnelling of carriers from 14 to 12. In the quantum well 12, the electrons relax to state E_1 as depicted by arrow 24. The relaxation results in the emission of electromagnetic radiation depicted by arrow 26 of energy hw. The wavelength of the emitted light will be inversely proportional to the energy difference E_2 - E_1. The recombined electrons in state E_1 then tunnel through layer 20 to electrode layer 16 as depicted by arrow 28. This is the only path for the electrons leaving state E_1 since state E_1 resides in the bandgap of layer 14 preventing electrons from tunnelling back to 14. Thus, very efficient carrier injection and optical transitions are achieved with a device formed with the band alignments in accordance with the present invention.

In the illustrative embodiment shown in Figure 2, the present invention is implemented with a combination of type I and type II tunnel junctions that use more than two different materials, forming polytype heterostructures. Polytype heterostructures were first disclosed by Esaki et al., Jp. J. of Appl. Phys. 20(7) 1981. A type I tunnel junction is such that under equilibrium the conduction band of the emitter is higher in energy than the valence band of the collector. In addition, a type I tunnel junction is formed with the conduction band of the collector higher in energy than the valence band of

the emitter. In contrast, in type II tunnel junctions, the conduction band of the emitter is lower in energy than the valence band of the collector or alternatively the conduction band of the collector is lower in energy than the valence band of the emitter.

An example of a type I tunnel junction is InAs-AlSb-InAs. An example of a type II tunnel junction is InAs-AlSb-GaSb. Both of these tunnel junctions are crystal-lattice compatible and may be routinely prepared by modern deposition techniques such as molecular beam epitaxy. The integration of these two tunnel junctions and material structure is shown in Figure 2. Electrode 14, tunnel barrier 18 and active region 12 are comprised of InAs-AlSb-InAs, respectively, a type I tunnel junction. At the same time, the quantum well region 12, barrier layer 20 and electrode 16 are comprised of InAs-AlSb-GaSb, respectively, a type II tunnel junction. Thus, the five layer light emitting device 10 is formed by a combination of the type I and type II tunnel junctions. As can be seen from the alignment of the conduction band E_C and the valence band E_V of each of the layers, the combination of type I and type II tunnel junctions allows for the realization of the conditions illustrated in Figure 1b. It will be obvious to those skilled in the art that other material systems from which type I and type II heterojunctions and tunnel junctions may be formed can be combined to provide the band edge arrangement of the present invention and the use of such other systems is contemplated herein.

Figure 2 is a calculated band diagram under dc bias of 140 mV. Active layer 12 is shown as having a thickness of 15 nm and barrier layers 18 and 20 are shown as having a thickness of 2 nm each. It should be understood that these thicknesses are exemplary only. Layer 14 is n-doped and layer 16 is p-doped. As with the thicknesses, the doping concentration shown for layer 14 of 5×10^{17} cm^{-3} and the doping for layer 16 of 1×10^{19} cm^{-3} are also exemplary only. Under a bias voltage V_b of 140 mV, and for energy difference of E_2 - E_1 equal to 0.12 eV, the corresponding light emission would be in the 10 μm range. By proper selection of material combinations, that may include alloys of the above InAs, GaSb and AlSb or other semiconductors compatible with them, and of the layer thicknesses, the light emission can be extended to both lower and longer wavelengths. Thus, emission near 1.8 μm can be achieved using a 5 nm InAs quantum well region 12 and AlGaAsSb as an injector layer 14 of carriers.

The preferred embodiment of the invention has been described above, however, several variations of the basic structure are possible. In one embodiment, a similar structure to that of Figure 2 is provided but having Gasb as the active layer 12

instead of InAs. The material structure is n-InAs/AlSb/GaSb/AlSb/p-Gasb. In this embodiment, the optical transitions will take place between hole states in GaSb as the two energy states E_1 and E_2 are located within the valence band of the active region. Upon applying a bias to this device, holes are supplied to the active region 12 from the electrode 16 at the higher energy level E_1, the holes then relax to the lower energy state E_2 to radiate electromagnetic energy inversely proportional to the energy difference between states. The holes are then collected by electrode 14 at an energy level of E_2.

In another variation, the invention may be implemented in a 2, 3 or 4 layer structure in which at least one junction is a type II heterojunction or a type II tunnel junction. A type II heterojunction has the same band edge offset requirement described above for the type II tunnel junction, except without the tunnelling layer being present. For example, the elimination of the Alsb barrier layer 18 in the structure of Figure 2, results in the optical transition occurring between quantum states in the accumulation layer formed at the interface of AlSb layer 20 and InAs layer 12. Likewise, the elimination of the AlSb barrier layer 20 in the structure of Figure 2, results in the optical transition taking place at the InAs layer 12 GaSb layer 16 interface. The elimination of both Alsb barrier layers 18 and 20 in the structure of Figure 2, will result in the optical transition occurring between quantum states in the accumulation layer formed at the interface of InAs layer 12 and GaSb layer 16. Where the tunnel layers are eliminated, carrier confinement is provided by a triangular potential barrier formed by band bending at the electrode and active region interface(s).

In another embodiment of the invention, tunnelling may be provided between the electrodes and the quantum well by the formation of zero thickness potential barriers. As shown by L. Chang and E. Mendez, IBM Tech. Bul. Vol. 32, No. 3B, August 1989, tunnelling may occur in two-dimensional systems by a zero thickness potential barrier between certain heterostructures. This concept is one method for realizing 3 and 4 layer devices of the invention.

A further embodiment includes the use of multilayer structures in layers 14 and 16 to manipulate and increase the refractive index of the cladding layers so that light guiding can be provided to the emitted radiation and e.g. low-threshold laser operation can be achieved. In addition, the use of short-period superlattices as electrodes layers 14 and 16 may be employed. In this system, the superlattices are designed in such a way that one of them has a mini-gap at the energy position of E_2 (see Figure 1) and a mini-band at the energy position of E_1, whereas the other one has a mini-

gap at E_1 and a mini-band at E_2.

Light detectors can be constructed utilizing the same basic principle. Figures 3a and 3b show band diagrams of a detector, Figure 3a being without bias and Figure 3b being in operation, i.e., with bias. As with the light emitting device of Figure 1, the detector 30 shown in Figure 3 is a five layer embodiment of the detector, with a quantum well region 32 separated by electrodes 34 and 36 and tunnel barriers 38 and 40. It should be noted that there is a difference in the material requirement from the light emitting structures of Figure 1. For light detection, the Fermi level E_F of the structure under equilibrium must be in the bandgap in either layer 34 or layer 36 to allow the application of a negative bias to the structure. Under a negative bias voltage, as shown in Figure 3(b), state E_1 is in the valence band of electrode 36 and in the bandgap of electrode 34, while state E_2 is in the bandgap of electrode 36 and in the conduction band of layer 34.

The arrangement of the bands as shown in Figure 3b under appropriate negative DC bias, provides for electrons in layer 36 to tunnel through layer 40 to state E_1 where they are excited to state E_2 by absorption of light of energy E_2 - E_1. The electrons then tunnel from state E_2 through layer 38 to layer 34. As in the case of the light emitting devices, the path available for electrons to reach electrode 34 is limited to the path depicted by arrows 42, 44 and 46, with absorption of photons with the proper energy depicted by arrow 48. This is due to the fact that state E_1 is in the bandgap of electrode 34 which prevents direct tunnelling from 36 to 34 and that energy state E_2 is in the bandgap of layer 36 preventing electrons from tunnelling back to 36. As can be seen, in the operating or biased state, both energy states E_1 and E_2 reside simultaneously in the bandgap of one electrode and in an allowed region of the other electrode.

The implementation of the invention for light detecting devices can also be made by a combination of type I and type II tunnel junctions. In the illustrative embodiment shown in Figure 4, the light detector 30 is formed by an AlInAsSb layer 34, an AlSb layer 38, an InAs layer 32, an Alsb layer 40 and a GaSb layer 36. As shown, the ground energy state E_1 lies in the bandgap of the AlInAsSb layer 34 and at the same time E_2 lies in the bandgap of the GaSb layer 36. Electrons are supplied from a GaSb layer 36 valence band to E_1 but are blocked by the bandgap of the AlInAsSb layer 34. As with the light emitter, other material systems are contemplated herein that will provide the band edge arrangement of the invention.

The energy band profile of Figure 4 is the calculated bands for a quantum well 32 of 8 nm, tunnel barriers 38 and 40 of 2 nm and under an

applied bias voltage of 400 mV. In this case E_2 - E_1 will be 0.345 eV, with a corresponding absorption wavelength of 3.59 μm. Similar variations in structure as described with respect to the light emitting devices also apply to the light detecting devices. Thus, the detectors may be formed by 3 and 4 layer structures of various combinations of type I and type II heterojunctions and type I and type II tunnel junctions as described above.

In accordance with the present invention, the optical transitions occur between discrete energy states in one of the allowed bands of the quantum well rather than between bands. The utilization of the energy states in this manner, together with the unique band alignment of the layers, allows for a much improved carrier injection efficiency. In addition, the wavelength of emission and absorption can be easily customized by selecting material systems and thicknesses to create the discrete energy levels necessary to provide the desired wavelength.

Furthermore, the opto-electronic devices of the invention can be made tunable to different wavelengths by the application of a moderate magnetic field perpendicular to the interfaces of the structures. A magnetic field allows for device tunability by permitting light emission or absorption between two magnetic levels (Landau levels). In addition, the presence of the magnetic field creates singularities in the density of the electronic states, which will enhance the efficiency of the device.

Analogous performance enhancement may be gained by further reduction of dimensionality of the electronic states in the well from two to one or zero dimensions, which would lead to singularities in the density of states. Such a reduction in dimensionality can be achieved by conventional lithographic techniques to produce quantum wires or quantum dots.

Although the implementation of the concepts of invention imposes certain limitations as to the materials systems that can be employed, the use of externally-produced stress or strained-layer heterostructures can expand the range of suitable materials. Finally, the inclusion of a third electrical terminal in the active region of the devices would provide an additional degree of freedom and will contribute to the optimization of device performance.

Claims

1. An optoelectronic device comprising:

a first region (14, 34) of semiconductor material
having conduction and valence allowed energy bands defined by corresponding band edges spaced apart by an energy bandgap;

a second region (16, 36) of semiconductor material having conduction and valence energy bands defined by corresponding band edges spaced apart by an energy bandgap; and

a quantum well active region (12, 32) of semiconductor material sandwiched between said first and second regions, said quantum well region having at least two energy states (E_1, E_2) under a bias voltage at least a first of said energy states residing within the bandgap of one of said first and second regions and simultaneously residing within one of said allowed energy bands of the other of said first and second regions.

2. The optoelectronic device of claim 1 wherein, under said bias voltage at least a second of said energy states resides within the bandgap of one of said first and second regions and simultaneously resides within one of the allowed energy bands of the other of said first and second regions.

3. The optoelectronic device of claim 2 wherein one of said first and second energy states resides in conduction band of one of said first and second regions and the other of said first and second energy states resides in the valence band of the other of said first and second regions.

4. The optoelectronic device of any one of the preceding claims further including at least a tunnel barrier disposed between said first or said second region and said quantum well region, preferably including a first tunnel barrier (18, 38) disposed between said first region and said quantum well region and a second tunnel barrier (20, 40) disposed between said second region and said quantum well region.

5. The optoelectronic device of claim 4 wherein said tunnel barriers are each comprised of a layer of semiconductor material having a bandgap wider than the bandgap of said quantum well region to provide carrier confinement and, to act as an insulator, said barriers being sufficiently thin to permit carrier tunnelling.

6. The optoelectronic device of any one of the preceding claims wherein said at least two energy states are located within one of the conduction band and the valence band of said quantum well region.

7. The optoelectronic device of any one of the preceding claims 4 to 6 wherein said first region, said first tunnel barrier and said quantum well region form a type I tunnel junction and wherein said quantum well region, said second tunnel barrier and said second region form a type II tunnel junction.

8. The optoelectronic device of any one of the preceding claims 4 to 7 wherein each of said tunnel barriers is formed by a zero thickness potential barrier.

9. The optoelectronic device of any one of the preceding claims further including means for applying a bias to said device sufficient to cause one of emission and absorption of electromagnetic energy between said first and second energy states in said quantum well region.

10. The optoelectronic device of claim 3 wherein said active region and at least one of said first region and said second region form a type II heterojunction.

11. The optoelectronic device of any one of the preceding claims wherein said first region is InAs, said second region is GaSb, said active region is one of InAs and GaSb, and, if present, said barrier layer is of ALSb.

12. The optoelectronic device of any one of the preceding claims 4 to 11 wherein said first region or said second region, respectively, said barrier layer and said active region form one of a type I and a type II tunnel junction.

13. The optoelectronic device of any one of the preceding claims 4 to 12 wherein said first region, said first barrier layer and said active region form a type II tunnel junction and wherein said active region, said second barrier layer and said second region form a type I tunnel junction.

14. The optoelectronic device of claims 2 or 4 wherein said first and second energy states are located within the conduction band of said active region, said device further including means for applying a bias to said device such that electrons are supplied to said active region from said first region at an energy level of about that of the higher of said first and second energy states, said electrons relaxing to the lower of said energy states thereby radiating electromagnetic energy inversely proportional to an energy of about the difference between the higher and lower energy states,

said electrons being collected by said second region at an energy level of about the lower of said energy states.

15. The optoelectronic device of claims 2 or 4 wherein said first and second energy states are located within the valence band of said active region, said device further including means for applying a bias to said device such that holes are supplied to said active region from said first region at an energy level of about that of the higher of said first and second energy states, said holes relaxing to the lower of said energy states thereby radiating electromagnetic energy inversely proportional to an energy of about the difference between the higher and lower energy states, said holes being collected by said second region at an energy level of about the lower of said energy states.

16. The optoelectronic device of any one of the preceding claims 1 to 10 wherein under equilibrium, the Fermi level resides in the band gap of one of said first and second regions.

17. The optoelectronic device of claim 16 wherein said first region is AlInAsSb, said second region and said active region is one of InAs and GaSb, and, if present, said barrier layer is of AlSb.

18. The optoelectronic device of claims 16 or 17 wherein said first and second energy states are located within the conduction band of said active region, said device further including means for applying a reverse bias to said device such that electrons are supplied to said active region from said second region at an energy level of about that of the lower of said first and second energy states, said electrons being excited to the higher of said energy states by an absorption of electromagnetic energy inversely proportional to an energy of about the difference between the higher and lower energy states, said electrons being collected by said first region an energy level of about the higher of said energy states.

19. The optoelectronic device of claims 15 or 16 wherein said first and second energy states are located within the valence band of said active region, said device further including means for applying a reverse bias to said device such that holes are supplied to said active region from said second region at an energy level of about that of the lower of said first and second energy states, said holes be-

ing excited to the higher of said energy states
by an absorption of electromagnetic energy
inversely proportional to an energy of about
the difference between the higher and lower
energy states, said holes being collected by
said first region at an energy level of about the
higher of said energy states.
